

Part 2: Mobile Project Development Setup and User Authentication

Project Title: MediBook: Health Appointment & Records Integration System

Student Name: Gyle M. Amihan

Course: IT342-[G01] Systems Integration and Architecture 1

GitHub Repository: <https://github.com/rig-gg/MediBook>

Date: July 2, 2026

Approved System/Project Description

MediBook is an integrated client-server healthcare ecosystem designed to bridge decentralized patient operations and administrative workloads into a unified platform. The system consists of a centralized Spring Boot REST API connected to a cloud-hosted Supabase PostgreSQL database, serving two frontend applications: a ReactJS web app for internal clinic management/administration, and an Android Kotlin mobile application for patient self-service. This submission covers the Android Kotlin mobile application component — specifically the project setup and the patient User Registration and User Login screens, connected to the Supabase backend via the Spring Boot REST API.

1. Android Studio Project Setup

2. Registration Screen (Patient Sign-Up)

3. Login Screen

4. Successful Registration / Registration Implementation

5. Successful Login / Login Implementation

6. Database or API Connection Proof

8. Short Development Progress Summary

For this part, I started by setting up the Android project in Android Studio using Kotlin, structured around the same MediBook system from my SRS. I organized the app into separate packages for the UI screens, network calls, and data models so it wouldn't turn into a mess later on. The main focus this week was getting the Registration and Login screens working for patient users, since those are the entry point into the rest of the mobile app.

For the backend, I connected the app to my Spring Boot REST API, which talks to the Supabase PostgreSQL database. Registration sends the patient's info (name, email, password, contact number) to the `/api/auth/register` endpoint, and login hits `/api/auth/login` and returns a JWT token that gets stored on the device for the authenticated session. I used Retrofit to handle the API calls from the Kotlin side.

I ran into a few issues along the way, mostly with network permissions and getting the emulator to actually reach the deployed backend, but after adjusting the base URL and adding internet permissions in the manifest, everything started working properly. Registration and login are both functional now, and successful login redirects the user to the next screen instead of just sitting on a static page. I committed progress to GitHub as I went so there's a record of the setup and the auth work getting built out.
